High Voltage High Current High and Low Side Driver

The NCP5183 is a High Voltage High Current Power MOSFET Driver providing two outputs for direct drive of 2 N-channel power MOSFETs arranged in a half-bridge (or any other high-side + low-side) configuration.

It uses the bootstrap technique to insure a proper drive of the High-side power switch. The driver works with 2 independent inputs to accommodate any topology (including half-bridge, asymmetrical half-bridge, active clamp and full-bridge...).

Features

- Automotive Qualified to AEC Q100
- Voltage Range: up to 600 V
- dV/dt Immunity ± 50 V/ns
- Gate Drive Supply Range from 9 V to 18 V
- Output Source / Sink Current Capability 4.3 A / 4.3 A
- 3.3 V and 5 V Input Logic Compatible
- Extended Allowable Negative Bridge Pin Voltage Swing to -10 V
 - ◆ Matched Propagation Delays between Both Channels
 - ◆ Propagation Delay 120 ns typically
 - ◆ Under V_{CC} LockOut (UVLO) for Both Channels
- Pin to Pin Compatible with Industry Standards
- These are Pb-free Devices

Typical Application

- Power Supplies for Telecom and Datacom
- Half-Bridge and Full-Bridge Converters
- Push-Pull Converters
- High Voltage Synchronous-Buck Converters
- Motor Controls
- Electric Power Steering
- Class-D Audio Amplifiers

MOSFET Turn On and Turn Off Current Path

A capacitor connected from VCC (VB) to GND (HB) terminal is source of energy for charging the gate terminal of an external MOSFET(s). For better understanding of this process see Figure 27 (all voltages are related to GND (HB) pin). When there is a request from internal logic to turn on the external MOSFET, then the Q_{source} is turned on. The current starts to flow from C_{VCC} (C_{boot}), through Q_{source} , gate resistor R_g to the gate terminal of the external MOSFET (depicted by red line). The current loop is closed from external MOSFET source terminal back to the C_{VCC} (C_{boot}) capacitor. After a while the C_{GS} capacitance is fully charged so no current flows this path. When the external MOSFET going to be turned off, the internal Q_{source} is turned off first

and after a short dead time Q_{sink} is turned on. Then C_{VCC} (C_{boot}) is not a source any more, the source of energy became the C_{GS} (and all capacitance connected to this terminal, like Muller capacitance). Now the current flows from gate terminal, through R_g resistor and Q_{sink} back to the MOSFET (depicted by blue line). In both cases (charging and discharging external MOSFET) there are several parasitic inductances in the path. All of them play a role during switching. In Figure 27 an influence of the inductances in some places is showed. On VCC (VB) pin a drop during turn on and turn off is observed. If too long an UVLO protection can be triggered and the driver can be turned off subsequently, which result in improper operation of the application.

Figure 27. Equivalent Circuit of Power Switch Driver

NCP5183, NCV5183

Layout Recommendation

The NCP5183 is high speed, high current (sink/source 4.3 A/4.3 A) driver suitable for high power application. To avoid any damage and/or malfunction during switching (and/or during transients, overloads, shorts etc.) it is very important to avoid a high parasitic inductances in high current paths (see “MOSFET turn on and turn off current path” section). It is recommended to fulfill some rules in layout. One of a possible layout for the IC is depicted in Figure 28.

- Keep loop HB_pin – GND_pin – Q_LO as small as possible. This loop (parasitic inductance) has potential to increase negative spike on HB pin which can cause of malfunction or damage of HB driver. The negative voltage presented on HB pin is added to $V_{CC} - V_f$ voltage so $V_{C_{boot}}$ is increased. In extreme case the C_{boot} voltage can be so high it will reach maximum rating value which can lead to device damage.
- Keep loop VDD_pin – GND_pin – C_{VCC} as small as possible. The IC featured high current capability driver.

Any parasitic inductance in this path will result in slow Q_LO turn on and voltage drop on VCC pin which can result in UVLO activation.

- Keep loop VB_pin – HB_pin – C_{boot} as small as possible. The IC featured high current capability driver. Any parasitic inductance in this path will result in slow Q_HI turn on and voltage drop on VB pin which can result in UVLO activation.
- Do not let high current flow through trace between GND_pin and C_{VCC} even a small parasitic inductance here will create high voltage drop if high current flows through this path. This voltage is added or subtracted from HIN and LIN signal, which results in incorrect thresholds or device damaging.
- Keep loops DRVL_pin – Q_LO – GND_pin and DRVH_pin – Q_HI – HB_pin as small as possible. A high parasitic inductance in these paths will result in slow MOSFET switching and undesired resonance on gate terminal.

Figure 28. Recommended Layout

C_{boot} Capacitor Value Calculation

The device featured two independent 4.3 A sink and source drivers. The low side driver (DRVL) supplies a MOSFET whose source is connected to ground. The driver is powered from V_{CC} line. The high side driver (DRVH) supplies a MOSFET whose source is floating from GND to bulk voltage. The floating driver is powered from C_{boot} capacitor. The capacitor is charged only when HB pin is pulled to GND (by inductance or the low side MOSFET when turned on). If too small C_{boot} capacitor is used the high side UVLO protection can disable the high side driver which leads to improper switching.

Expected voltage on C_{boot} is depicted in Figure 29. The curves are valid for ZVS (Zero Voltage Switching) observed in LLC applications. For hard switch the curves are slightly different, but from charge on C_{boot} point of view more

favorable. Under the hard switch conditions the energy to charge Q_g (from zero voltage to V_{th} of the MOSFET) is taken from V_{CC} capacitor (through an external boot strap diode) so the voltage drop on C_{boot} is smaller. For the calculation of C_{boot} value the ZVS conditions are taken account.

The switching cycle is divided into two parts, the charging (t_{charge}) and the discharging (t_{discharge}) of the C_{boot} capacitor. The discharging can be divided even more to discharging by floating driver current consumption I_{B2} (t_{dsIb}) and to discharging by transferring energy from C_{boot} to gate terminal of the MOSFET (t_{dsQm}). Discharging by I_{B2} becoming more dominant when driver runs at lower frequencies and/or during skip mode operation. To calculate C_{boot} value, follow these steps:

Figure 29. Boot Strap Capacitor Charging Principle

1. For example, let's have a MOSFET with Q_g = 30 nC, V_{DD} = 15 V.
2. Charge stored in C_{boot} necessary to cover the period the C_{boot} is not supplied from V_{CC} line (which is basically the period the high side MOSFET is turned on). Let's say the application is switching at 100 kHz, 50% duty cycle, which means the upper MOSFET is conductive for 5 μs. It means the C_{boot} is discharged by I_{B2} current

(81 μA typ) for 5 μs, so the charge consumed by floating driver is:

$$Q_b = I_{B2} \cdot t_{discharge} = 81\mu \cdot 5\mu = 405 \text{ pC} \quad (\text{eq. 1})$$

3. Total charge loss during one switching cycle is sum of charge to supply the high side driver and MOSFET's gate charge:

$$Q_{tot} = Q_g + Q_b = 30\text{n} + 405\text{p} = 30.4 \text{ nC} \quad (\text{eq. 2})$$

4. Let's determine acceptable voltage ripple on C_{boot} to 1% of nominal value, which is 150 mV. To cover charge losses from eq. 2

$$C_{boot} = \frac{Q_{tot}}{V_{ripple}} = \frac{30.4n}{0.15} = 203 \text{ nF} \quad (\text{eq. 3})$$

It is recommended to increase the value as consumption and gate charge are temperature and voltage dependent, so let's choose a capacitor 330 nF in this case.

R_{boot} Resistor Value Calculation

To keep the application running properly, it is necessary to charge the C_{boot} again. This is done by external diode from V_{CC} line to VB pin. In serial with the diode a resistor is placed to reduce the current peaks from V_{CC} line. The resistor value selection is critical for proper function of the high side driver. If too small high current peaks are drawn from V_{CC} line, if too high the capacitor will not be charged to appropriate level and the high side driver can be disabled by internal UVLO protection.

First of all keep in mind the capacitor is charged through the external boot strap diode, so it can be charged to a maximum voltage level of $V_{CC} - V_f$. The resistor value is calculated using this equation:

$$R_{boot} = \frac{t_{charge}}{C_{boot} \cdot \ln\left(\frac{V_{max} - V_{Cmin}}{V_{max} - V_{Cmax}}\right)} = \frac{5\mu}{330n \cdot \ln\left(\frac{14.4 - 14.2}{14.4 - 14.35}\right)} \cong 11 \Omega \quad (\text{eq. 4})$$

Where:

t_{charge} – time period the C_{boot} is being charged, usually the period the low side MOSFET is turned on

C_{boot} – boot strap capacitor value

V_{max} – maximum voltage the C_{boot} capacitor can be theoretically charged to. Usually the $V_{CC} - V_f$. The V_f is forward voltage of used diode.

V_{Cmin} – the voltage level the capacitor is charged from

V_{Cmax} – the voltage level the capacitor is charged to. It is necessary to determine the target voltage for charging, because in theory, when a capacitor is charged from a voltage source through a resistor, the capacitor can never reach the voltage of the source. In this particular case a 50 mV difference (between the voltage behind the diode and V_{Cmax}) is used.

The resistor value obtained from eq. 4 does not count with the quiescent current I_{B2} of the high side driver. This current will create another voltage drop of:

$$V_{IB2_drop} = R_{boot} \cdot I_{B2} = 11 \cdot 81\mu \cong 0.9 \text{ mV} \quad (\text{eq. 5})$$

The current consumed by high side driver will be higher, because the I_{B2} is valid when the device is not switching. While switching, losses by charging and discharging internal transistors as well as the level shifters will be added. This current will increase with frequency.

The additional 0.9 mV drop will be added to V_{Cmax} value. The additional 0.9 mV drop can be either accepted or the

R_{boot} value can be recalculated to eliminate this additional drop.

The resistor R_{boot} calculated in eq. 4 is valid under steady state conditions. During start and/or skip operation the starting point voltage value is different (lower) and it takes more time to charge the boot strap capacitor. More over it is not counted with temperature and voltage variability during normal operation or the dynamic resistance of the boot strap diode (approximately 0.34 Ω for MURA160). From these reasons the resistor value should be decreased especially with respect to skip operation.

Boot strap resistor losses calculation.

$$P_{Rboot} \cong Q_{tot} \cdot V_{Cmax} \cdot f = 30.4n \cdot 14.4 \cdot 100k \cong 44 \text{ mW} \quad (\text{eq. 6})$$

Boot strap diode losses calculation.

$$P_{Dboot} \cong Q_{tot} \cdot V_f \cdot f = 30.4n \cdot 0.6 \cdot 100k \cong 1.8 \text{ mW} \quad (\text{eq. 7})$$

Please keep in mind the value is temperature and voltage dependent. Especially C_{boot} voltage can be higher than calculated value. See "Layout recommendation" section for more details.

Total Power Dissipation

The NCP5183 is suitable to drive high input capacitance MOSFET, from this reason it is equipped with high current capability drivers. Power dissipation on the die, especially at high frequencies can be limiting factor for using this driver. It is important to not exceed maximum junction temperature (listed in absolute maximum ratings table) in any cases. To calculate approximate power losses follow these steps:

1. Power loss of device (except drivers) while switching at appropriate frequency (see Figure 26) is equal to

$$P_{logic} = P_{HS} + P_{LS} = (V_{boot} \cdot I_{B2}) + (V_{CC} \cdot I_{CC2}) = (14.4 \cdot 1.6m) + (15 \cdot 0.6m) \cong 32.1 \text{ mW} \quad (\text{eq. 8})$$

2. Power loss of drivers

$$P_{drivers} = ((Q_g \cdot V_{boot}) + (Q_g \cdot V_{CC})) \cdot f = ((30n \cdot 14.4) + (30n \cdot 15)) \cdot 100k \cong 88 \text{ mW} \quad (\text{eq. 9})$$

3. Total power losses

$$P_{total} = P_{logic} + P_{drivers} = 32.1m + 88m \cong 120 \text{ mW} \quad (\text{eq. 10})$$

4. Junction temperature increase for calculated power loss

$$t_J = R_{tJa} \cdot P_{total} = 183 \cdot 0.12 \cong 22 \text{ K} \quad (\text{eq. 11})$$

The temperature calculated in eq. 11 is the value which has to be added to ambient temperature. In case the ambient temperature is 30°C, the junction temperature will be 52°C.
